Chapter 1

Introduction

1.1 Motivation

Automatic text correction is a ubiquitous technology in our today world. Every smartphone, every word processing software, every browser provides some form of spelling error detection and correction for text input and these tools have proven to be very useful for both language learners and native speakers. These systems usually rely on a dictionary of correct words [7, 6] or some machine learning algorithm [27] to find errors and possible corrections.

Source code is very sensitive to syntax, semantic and logical errors (see Table 1.1 for definition) and therefore a similar functionality is desirable for code editors. The syntax of a programming language is strictly defined which enables integrated development environments (IDEs) to detect syntax errors before the program is even run. Of course the possibilities of an IDE are limited by the properties of the programming language, e.g. is it strongly typed or weakly typed. However, the error detection in source code is mostly limited to syntax errors, while semantic and logical errors show only at runtime or sometimes go completely unnoticed. These kinds of errors are also the hardest ones to fix. In a strongly typed language like Java, a lot of possible errors in naming and accessing attributes can be eliminated, because each variable has to be initiated before it is used and the type of the variables is known at all times and therefore also their available attributes and methods. In weakly typed languages like Ruby however, one can not determine what type of object a variable holds before runtime. This creates additional sources of runtime errors.

While syntax errors can be detected by a suitable algorithm, traditional algorithms can only hope to help prevent semantic and logical errors. This is where machine learning algorithms could step in. In the past years, deep neural networks have proven to be very effective in learning generalised concepts and applying them to single cases. For example in [23] a network is trained to transfer the style of a painting to a video sequence. That's why it should also be possible to train a network to recognize and correct certain logic errors in source code.

The aim of this project is it to train a character based sequence-to-sequence model on the task of source code correction. The implementation of the model is based on the neural machine translation (NMT) model provided by Tensorflow

Error Type	Definition	Example
syntax	Violation of the specified syntax of the programming language.	<pre>public int add(int a, int b){ int sum := a + b; return sum; }</pre>
semantic	Incorrect usage of a variable or statement.	<pre>public void add(int a, int b){ int sum = a + b; return sum; }</pre>
logical	Failure to comply with the programs requirements.	<pre>public int add(int a, int b){ int sum = a - b; return sum; }</pre>

Table 1.1: The definition of syntax, semantic and logical error in the context of programming languages.

[16]. As a dataset the Java Github Corpus [1] is used as a source of correct data. This data is then perturbed as random syntax, semantic and logic errors are added. The performance of different model architectures is then evaluated for the introduced errors.

1.2 Outline

This thesis is divided into five chapters, including this introduction. In the second chapter an overview of the prior work on the task of spelling checking and correction is given and also some work on error detection and correction in source code. Furthermore a short introduction to the machine learning techniques and architectures used in this thesis is given. The third chapter provides a description of the used model, the training procedure and the dataset construction. In chapter four the experiments are explained and the obtained results analysed. Chapter five provides the conclusion and suggestions for future work.

Chapter 2

Background

2.1 Origins of Spelling Checkers and Correctors

With the emergence of word processing programs and the following digitalization of text documents, spelling checkers and correctors have become a common helper in our everyday lives. However, the research on this topic has begun much earlier [20].

The original motivation for a spelling checker was to find input errors in databases. For example, in [4] the authors aim to find incorrectly spelled names, dates and places in a genealogical database. This is done by computing the frequency of trigrams (three sequential characters) in the source text and based on that the probability of a character given some context, i.e. its adjacent characters. Erroneous words are found by looking at its trigrams. If a word consist of a number of unusual character combinations, it is probably spelled wrongly. However, it is easy to see that this method is not very useful for new, rare or foreign expressions like **doppelgänger** and for typos with high probabilities of being correct. Furthermore the model is limited to the vocabulary used in the text.

These problems were solved by the introduction of dictionaries. A dictionary is a list of correctly spelled words which can optionally be extended by the user. For every word, the program checks if it is part of the dictionary. If it is, then it is spelled correctly, otherwise there is an error. This method was enhanced by the addition of direct user interaction. Instead of outputting a list of incorrect words, the program would show the user the words it assumed to be incorrectly spelled and then give the user some possible actions to chose from.

Spelling correction is another enhancement of these methods. In [7] a dictionary is used to find incorrect words. It is assumed that these words contain only one of four types of errors: one character was wrong, one extra character was inserted, one character was missing or two adjacent characters were transposed. Under this assumption the dictionary is searched for possible corrections. In [6] the author uses a dictionary to find incorrect words as well. For the found words he uses digrams (similar to the trigrams mentioned above, just with two instead of three characters) to suggest corrections for incorrect words.

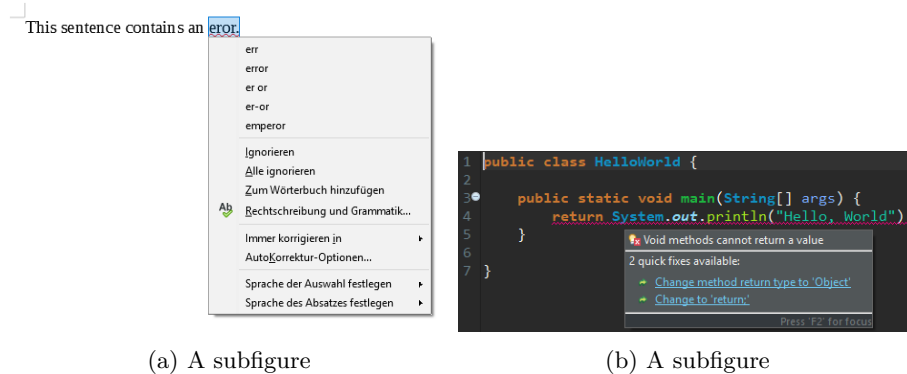

Figure 2.1: A figure with two subfigures

2.1.1 Modern Research

Of course the methods described so far do still not take the context of the text into account. For example if **know** is misspelled as **now**, no error is indicated even though it could be concluded from the context that a verb is expected in this place. This "context-awareness" has been the topic of a lot of recent research. In [3] n-grams are used to determine the most likely replacement for an error and in [9] the authors concentrate on finding and correcting small spelling errors that result in correct words and are therefore not detected by a traditional spelling checker (e.g. **to** for **too** or **there** for **their**). Other researchers concentrated on a particular set of errors like article [10] or preposition errors [22].

However, even though these methods perform well on the errors they were designed for, a large amount of different classifiers is needed to catch every error. This is a costly and inflexible approach. Recent research often uses statistical machine translation methods or language models and n-grams to correct errors of multiple classes [25]. In [27] the authors train an encoder-decoder neural network with an attention mechanism which operates at the character level. [8] chose a similar approach applied to keyboard decoding on smartphones.

2.2 Automatic Correction of Source Code

Of course automatic error correction is also a useful helper for writing code. Because of the well-defined syntax of a programming language, syntactical errors are relatively easy to find using an algorithm. This functionality can help novice programmers to avoid typical beginner's errors like a missing semicolon at the end of the line. However, semantic and logical errors can usually not be detected this easily.

The correctability of a programming language depends in part on its properties. One important distinction is between strongly typed and weakly typed programming languages [15]. In a strongly typed programming language, every variable has a fixed type and every method has a fixed return type. This enables an editor program to check if the expected and the actual type match before runtime. This error can then be flagged and shown to the user. In contrast, in a weakly typed programming language, variables don't have a fixed type.

They can contain whatever value one assigns to them and similarly methods can take arguments of any type and also return values of any type. In this case, an error of an operation which gets an unexpected parameter type only shows at runtime. For example on the one hand, the type error in

```
public int increment(int a){  
    return ++a;  
}  
int result = increment("a");
```

can be detected before runtime because Java is a strongly typed programming language. The type of the parameter `a` is defined as `int` and the method invocation with an argument of type `String` is clearly wrong. On the other hand the type error in

```
a = 10  
print("The number ten: " + a)
```

shows only at runtime. Python is a weakly typed language and in general it can not be determined what type of value a variable holds before runtime. Only when the code is executed, the `+` operator looks at its arguments and throws an error if their types don't match.

Chapter 3

Model and Training

3.1 Components

3.1.1 LSTM

A recurrent neural network (RNN)[26] is a special form of neural network that is used for sequential tasks. It works by having multiple copies of the network, one for each timestep. As the input proceeds in time, each network passes information to its next instance as seen in **INSERT FIGURE HERE**. For an input sequence $(\mathbf{x}_1, \dots, \mathbf{x}_n)$ the RNN produces at each timestep t a hidden state vector \mathbf{h}_t as follows:

$$\mathbf{h}_t = \tanh\left(\mathbf{W}\begin{pmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{pmatrix}\right)$$

However, RNNs have proven to be hard to train, especially on long-range dependencies [11]. In theory, they should be able to deal with these dependencies but either vanishing or exploding gradients usually prevent them from doing so. To solve this issue, Long Short-Term Memory networks (LSTMs) [12] were proposed. In addition to \mathbf{h}_t , LSTMs also pass a memory state vector \mathbf{c}_t to the next instance as can be seen in **INSERT FIGURE HERE**. The LSTM can choose at each timestep if it wants to read or forget information from the memory vector or write new information onto the vector. This is done by using explicit gating mechanisms:

$$\begin{aligned} \mathbf{f}_t &= \sigma\left(\mathbf{W}_f\begin{pmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{pmatrix}\right) & \mathbf{i}_t &= \sigma\left(\mathbf{W}_i\begin{pmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{pmatrix}\right) \\ \mathbf{o}_t &= \sigma\left(\mathbf{W}_o\begin{pmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{pmatrix}\right) & \mathbf{g}_t &= \tanh\left(\mathbf{W}_g\begin{pmatrix} \mathbf{x}_t \\ \mathbf{h}_{t-1} \end{pmatrix}\right) \end{aligned}$$

where σ is the sigmoid function. \mathbf{f}_t , \mathbf{i}_t and \mathbf{o}_t can be thought of as binary gates that decide which information from \mathbf{c}_{t-1} should be deleted, which information of \mathbf{c}_{t-1} should be updated and which information from \mathbf{c}_t should be written to \mathbf{h}_t . Finally \mathbf{g}_t is a vector of possible values that (gated by \mathbf{i}_t) can be added to \mathbf{c}_{t-1} and because of the tanh in the equation its values may range from -1 to 1. The state vectors are then updated as follows:

$$\begin{aligned}\mathbf{c}_t &= \mathbf{f}_t \odot \mathbf{c}_{t-1} + \mathbf{i}_t \odot \mathbf{g}_t \\ \mathbf{h}_t &= \mathbf{o}_t \odot \tanh(\mathbf{c}_t)\end{aligned}$$

Almost all remarkable results that are achieved today are achieved using either LSTMs or networks with a similar architecture like Gated Recurrent Units (GRUs) [5] because they are easier to train and excel at capturing long range dependencies.

3.1.2 The Sequence-to-Sequence Model

Traditional Deep Neural Networks (DNNs) process the whole input and then calculate some output, e.g. process an image and then classify it. This works well for problems where the input and the output are of a fixed dimension, however it is not suitable for problems where the input and the output are sequences of variable length. An example would be the input of a question and the network should produce an answer. We have seen that we can use LSTMs to process input sequences of variable length. However, in this case we want to process the whole input sequence and all the information that comes with it and only then start generating an output sequence. These problems are called sequence to sequence problems.

In [24] the Sequence-to-Sequence Model is introduced as a solution to these problems. The model was applied to the task of Neural Machine Translation (NMT) and has since become the state of the art architecture in this field. The main concept can be seen in **FIGURE X**. First the whole input sequence is fed into the network and the output is ignored. Then we input an end-of-sequence token `<EOS>` which signals the network to start producing the output. From there on the produced output tokens are fed to the network until the an end-of-sequence token is generated, thus signaling the end of the sequence. To speed up training the expected output is fed back to the network and not the actual produced output.

This architecture is further improved by splitting the network into two separate LSTMs (**FIGURE**). The first network takes all the input and encodes it into a vector which is then used to initialize the second network. It is first fed a start token `<GO>` and then the generated output until the end of the sequence is reached.

The network usually operates at word level and uses some word embedding like word2vec [18]. This method has the advantage of giving the input words some meaning through the embedding instead of just inputting a meaningless encoding of the word. While this is very effective for translation tasks, there are some limitations to this method. These embeddings work on a fixed size vocabulary which means that out of vocabulary words (OOV) can't be handled. Also special character sequences like :) pose a problem.

3.1.3 Attention-Mechanism

Attention is a relatively new concept for neural networks. The idea is to allow the network to chose on which information to focus at any given moment. For example in [19] attention is used on the task of high resolution image classification. These kind of networks often struggle with memory constraints and

attention can help them to only load the significant part of the image into the memory.

Attention has subsequently been applied to NMT [17, 2]. The vector into which the input is encoded in the Sequence-to-Sequence model has been identified as a bottleneck which cuts down performance because of its limited capacity. After all the vector is of fixed dimensionality and needs to encode information about the whole input sequence. Because of that attention is used as a mean for the decoder to peek at previous hidden states of the encoder. This is done via a context vector $\tilde{\mathbf{c}}_t$ which is combined with the current hidden state of the decoder \mathbf{h}_t . The resulting attentional hidden state $\tilde{\mathbf{h}}_t$ is then used by the decoder to generate the next output.

$$\tilde{\mathbf{h}}_t = \tanh \left(\mathbf{W}_c \begin{pmatrix} \tilde{\mathbf{c}}_t \\ \mathbf{h}_t \end{pmatrix} \right)$$

For the derivation of the context vector $\tilde{\mathbf{c}}_t$ all hidden states of the encoder $\bar{\mathbf{h}}_s$ are considered. For this an alignment vector \mathbf{a}_t , whose size equals the input sequence length, is calculated from the current decoder hidden state \mathbf{h}_t and the encoder hidden states $\bar{\mathbf{h}}_s$. The values of a_t are then normalized using the **softmax** function.

$$a_t(s) = \frac{\exp(\text{score}(\mathbf{h}_t, \bar{\mathbf{h}}_s))}{\sum_{s'} \exp(\text{score}(\mathbf{h}_t, \bar{\mathbf{h}}_{s'}))}$$

Here, **score** is a content-based function used to compare the decoder hidden state \mathbf{h}_t with each of the encoder hidden states $\bar{\mathbf{h}}_s$. There are various possible choices for this function, for example:

$$\text{score}(\mathbf{h}_t, \bar{\mathbf{h}}_s) = \begin{cases} \mathbf{h}_t^\top \mathbf{W}_a \bar{\mathbf{h}}_s \\ \mathbf{v}_a^\top \tanh \left(\mathbf{W}_a \begin{pmatrix} \mathbf{h}_t \\ \bar{\mathbf{h}}_s \end{pmatrix} \right) \end{cases}$$

The context vector \mathbf{c}_t is then calculated as the weighted average over the encoder hidden states.

$$\mathbf{c}_t = \sum_{s'} a_t(s') \bar{\mathbf{h}}_{s'}$$

3.2 Implementation

.....

Ich erkläre hiermit, dass ich diese Arbeit selbständig verfasst und keine anderen als die angegebenen Quellen benutzt habe. Alle Stellen, die wörtlich oder sinngemäss aus Quellen entnommen wurden, habe ich als solche gekennzeichnet. Mir ist bekannt, dass andernfalls der Senat gemäss Artikel 36 Absatz 1 Buchstabe o des Gesetzes vom 5. September 1996 über die Universität zum Entzug des auf Grund dieser Arbeit verliehenen Titels berechtigt ist.
